(E) Ideal result of our work

// Report 1 (source: intezer.com)

RedXOR uses an open-source LKM rootkit called “Adore-ng” to **hide** its process. Embedding open-source LKM rootkits is a common Winnti technique. The **malware** checks if the **rootkit** is active by creating a **file** and removing it. Then, the **malware** compares the “saved set-user-ID” of the process to the user ID. If they don’t **match**, the **rootkit** is enabled. As part of its persistence methods, RedXOR attempts to create a service under **rc.d**. The developer added “**S99**” before the name of the service to lower its **priority** and make it run **last on system** initiation.

// Report 2 (source: microsoft.com)

Some XorDdos samples install a **kernel** rootkit, while others **embed** the rootkit in the XorDdos binary. In this case, the malware has a **provision for communicating with** its rootkit component **/proc/rs_dev** by **sending** input and **output control** (IOCTL) calls with additional **information** to take appropriate action. XorDdos uses various persistence mechanisms to support different Linux distributions. The malware **drops** an init script at the location **/etc/init.d**. It **creates** a cron script at the location **/etc/cron.hourly/gcc.sh** then **creates** a **/etc/crontab** file to **run** **/etc/cron.hourly/gcc.sh** every three minutes.
